Defence Science Technology Group investigating functional changes associated with microbiologically influenced corrosion in marine environments.

**Associate Professor Ashley E Franks** is head of the Applied and Environmental Microbiology Laboratory at La Trobe University. He conducted his doctorate research as part of the Centre of Marine Biofouling and Bioinnovation at the University of New South Wales by investigating antifungal compounds produced by marine bacteria in biofilms. During his PhD he spent 4 months at the University of Exeter in the UK on an Adrian Lee Fellowship to develop dual bacterial/yeast biofilm systems. On graduating he moved to the Biomerit Research Centre in Cork, Ireland to work on bacterial plant interactions as a Government of Ireland Fellow in Science Technology and Engineering. This research looked at how to use bacteria to help plant growth. He then took a position as a Senior Scientist and Research Professor within the Geobacter Project at the University of Massachusetts Amherst in the USA where he worked on microbes that make electricity. He currently serves as the Chair of the Awards Committee for the International Society of Microbial Electrochemical Technology and was previously the Secretary of Synthetic Biology Australasia.

Recently, the role of the plant-associated mycobiome (i.e. the fungal community) in influencing the competitive success of invasive plant species has received increasing attention. Fungi act as primary drivers of the plant invasion process due to their ability to form both beneficial and detrimental relationships with terrestrial plant species. Here we review the role of the plant mycobiome in promoting or inhibiting plant species invasion into foreign ecosystems. Moreover, the potential to exploit these relationships for invasive plant control and restoration of native communities is discussed. Incorporating fungal community ecology into invasion and restoration biology will aid in the management and control of invasive plant species in Australia.

Alien invasive plant species represent an ever-increasing worldwide problem. The expansion of invasive species in non-native ranges can dramatically alter the structure and population dynamics of the invaded community, with the negative impact of invasive plants on ecosystem structure and function resulting in changes to native vegetation composition and productivity, nutrient cycling, soil characteristics, and even human well-being.\(^1\)

Many factors regulate exotic species naturalisation and invasion success, including the ability to rapidly access resources, allelopathy, and the modification of ecosystem processes (reviewed in Levine *et al*.\(^2\)). However, an increasing body of evidence suggests a pivotal role for the plant-associated mycobiome (i.e. the fungal community) in influencing the competitive success of invasive species\(^3\text{-}^6\). Fungi are important terrestrial ecosystem components, acting as mutualists, pathogens, decomposers, and food sources. Because of their primary role as drivers of many ecosystem functions and their ability to establish intimate relationships with terrestrial plant species (e.g. mycorrhizal fungi or leaf endophytes) (Figure 1), fungal communities can critically influence plant fitness and survival and, hence, their colonisation and invasion patterns.\(^5\text{-}^7\).
Understanding the mechanistic interactions underpinning the invasion process is predicted to be particularly important for Australia, where invasive species pose not only a threat to the biodiversity of its unique vegetation, but also an economic problem. Following accidental and deliberate introductions after European colonisation of the continent, approximately 2700 exotic plant species are now considered established within the continent, with almost 250 having been declared harmful or being under some form of legal control measure. In terms of economic burden, the control of alien plant species is calculated to cost approximately AU$4 billion annually for agriculture alone. The cost associated with managing native plant communities, although difficult to estimate, is predicted to also be considerable.

Given the environmental and economic implications of invasive plant species control, the need to find effective strategies for the prevention, early detection, and eradication of invasive species now represents a priority in many economic and scientific agendas. Here we discuss the role of the plant mycobiome in promoting or inhibiting invasive plant species incursion into foreign ecosystems, and propose ways through which these relationships can be exploited for invasive plant control and native communities restoration.

**Mechanisms and effects of fungi-plant interaction during invasion**

**Pathogenic relationships:** The interactions between invasive species and their fungal communities are complex, with invasion success often being defined by the nature of such relationships. For example, during invasive plant establishment, pathogenic fungi can form novel associations detrimental to the invasive plants. This possibility is usually amplified if the invasive and native plants are not phylogenetically related, resulting in specific targeting of the invasive species, and thus prevention of invasion through inhibition (Figure 2). In contrast, successful invasion is often promoted by the loss of detrimental microbes, such as pathogenic fungi, particularly when they are not present in the newly colonised habitat. Invasive species can also act as reservoirs for microorganisms that are pathogenic for the invaded community, with a consequent enhancement of the negative impact of invasion on the native vegetation, as observed during the invasion of non-native *Spartina alterniflora* and its fungal pathogen (*Fusarium palustre*) on native Chinese saltmarsh plants. This instance implies the ability of the invader population to resist or tolerate native pathogens within the invaded areas, causing an increase in pathogen loads detrimental to the native community.
Symbiotic relationships: An equally important aspect of the plant-fungi relationship during the invasion process pertains to the role of symbiotic interactions, such as mycorrhizal interactions. Mutualism preservation is often vital for the invaders, and the occurrence of such beneficial interactions in the invaded habitat can be enhanced by the presence of native arbuscular mycorrhizal fungi with low endemism and low specificity in their range of associations. 

Invading plants able to form novel symbiotic associations are also typically more successful. This strategy is particularly relevant for arbuscular mycorrhizal plants, which tend to establish novel associations in their exotic range, resulting in increased fitness and enhanced invasiveness, such as in the case of the invasive North American species *Ambrosia artemisiifolia*. Alternatively, the co-introduction of associated symbionts in the colonised habitat may favour the invasive plants. Co-introduction is usually due to the transport of infected plants or propagules, or from the translocation of contaminated soil. The presence of a suitable symbiotic partner, either native or alien, can significantly enhance invader fitness in the newly colonised habitat, as observed in the case of non-native willows introduced with their native fungal symbionts in Southern Australia riparian systems.

In some instances, co-introduced symbionts may also be able to modify the native microbial community structure, including...
substantial loss of belowground diversity and native mutualists, with detrimental repercussions for the native host’s fitness. Such invasive processes can result in negative modifications of the functional attributes of the invaded system. For example, the invasion of non-ectomycorrhizal communities by ectomycorrhizal plants causes both a decrease in soil carbon and a co-release of nutrients from the soil. Plant-fungus co-invasion may also cause shifts in the total plant biomass; a change either enhanced by the increase in mutualistic fungi or decreased by the pathogenic invaders. Both the biomass shift and the plant compositional modification can critically alter important ecosystem processes in the native community invaders.

**Implications for management**

A better understanding of plant-fungi interactions can have important repercussions for the mitigation of negative impacts of invasive plants and the design of better restoration strategies. Novel microbe-mediated approaches for invasive plant control may include the inhibition of fungal symbiotic relationships that provide competitive advantages to invasive plant species (e.g. through the introduction of pathogenic microbes or inhibition of beneficial fungi). In particular, the co-introduction of native pathogens has been proposed as an effective strategy to manage alien plant species. An example of the successful application of fungi as biocontrol agents is represented by *Phragmidium violaceum*, used to control invasive blackberry trees in Australia. Similarly, the rust fungus *Uromyces penceanus* has been proposed as a promising biocontrol agent to reduce the spread of *Nassella neesiana* (Chilean needle grass), a grass species invasive to the southern hemisphere.

In addition to the invading plant management, the plant-mycobiome relationship can be harnessed to mitigate the legacies of disrupted fungal communities resulting from processes such as plant-fungi co-invasion. Effective restoration strategies may be represented by manipulations targeted to increase the fitness of native plants. Particularly, the effectiveness of using native inocula to improve the establishment, growth and diversity of plants in their native range has been demonstrated in many instances (e.g. see Maltz and Treseder), offering an alternative approach to the native community re-establishment. In this sense, national initiatives such as the ‘Biomes of Australian Soil Environments’ (BASE) project may offer a useful baseline to explore the Australian microbial biodiversity and map the occurrence of suitable microbial partners in potential reintroduction ranges, thus facilitating the selection of reintroduction locations that support a fungal community similar to the native plant community of origin.

**Conclusions**

In the past decade, a mounting body of evidence from ecological studies has contributed to unravelling the pivotal contribution of the plant-fungus interaction in mediating the successful plant invasion. Much of this novel insight converged to recognise that invasion dynamics cannot be understood or predicted without a thorough characterisation of the relationships occurring between invasive and native plants together with their respective microorganisms. We therefore believe that approaching the plant-fungus relationships during invasion ecology studies in a mechanistic framework represents a fundamental prerequisite to better understand the processes underpinning the competitive success of invasive plant species, and thus design effective and long-lasting management and restoration strategies. Particularly, the characterisation of the microbial diversity and temporal variability, including endophytes and rhizosphere microbes, relevant to both the invasive and native plants at different growth stages, as well as the identification of their functional role and their effect on plant growth, development and tolerance, will represent the foundation to design effective microbiome manipulation strategies and predict possible invasion outcomes. Exploring new venues to protect and restore native vegetation communities may be particularly relevant for Australia, a continent where many terrestrial systems are experiencing a rapidly increasing environmental pressure related to climate change, habitat loss and fragmentation, and growing human populations. Further research focused on elucidating the impact of linked plant-fungal invasions in the context of ecosystem-level and community assembly processes holds promise to provide a solid scientific framework to predict invasion trajectories, and thus improve the outcomes of alien plant invasion management approaches.
